Abstract

This work presents a combined experimental and numerical approach to the design and analysis of tape-laid thermoplastic composite cryogenic tanks. A detailed material and defect characterisation of automated tape-laid CF/PEEK is undertaken using optical micrography and 3D X-ray CT (computed tomography) as well as cryogenic testing to investigate damage formation. Resulting material data is used as input for a novel XFEM (extended finite element method)-cohesive zone methodology which is used to predict intra- and inter-ply damage in an internally pressurised cryogenic tank. An optimised tank lay-up is presented and analysed using the numerical method to ensure resistance to microcrack formation and fuel leakage through the tanks walls under operating loads.

Keywords: B. Defects; C. Finite element analysis (FEA); D. Non-destructive testing; E. Lay-up (manual/automated).

1. Introduction

Due to their high specific strength and stiffness amongst other properties, carbon-fibre reinforced polymers (CFRP) are seen as candidate materials for the fuel tanks of next generation reusable launch vehicles (RLVs). These fuel tanks will be exposed to cryogenic temperatures as low as $-250\text{ }^{\circ}\text{C}$ and to internal pressurisation as high as 1 MPa. This extreme thermo-mechanical loading can lead to microcracking and delamination formation within the CFRP, which, in severe cases, can result in permeation of the cryogen through the fuel tank walls. A precise understanding, therefore, of the methods of damage accumulation in the material and how the various damage modes interact underpins the potential use of CFRP for RLVs.

While numerous works have been published on the design and testing of composite overwrapped pressure vessels (COPVs) [1-4], the unique challenges posed by cryogenic fuel storage have yet to be fully addressed. Work on the design and analysis of composite cryo-tanks has intensified since the failure of the NASA/Lockheed X-33 RLV fuel tank [5], where fuel leakage occurred due to cryogenically induced damage in the composite tank wall. Subsequent experimental and theoretical analyses of cryo-tanks [6, 7] have found that, unlike traditional COPVs, the thermal stresses induced by cryogenic loading are the main design consideration and play a critical role in damage formation. In addition, the role of material quality and processing conditions on damage initiation remain understudied [8, 9], particularly for advanced thermoplastic composites such as CF/PEEK, which are increasingly used in conjunction with novel processing techniques such as automated tape laying (ATL) for the manufacturing of large structures.

Thermoplastic composites offer several advantages over thermosets in terms of their improved range of properties and processing techniques available. CF/PEEK is a high-performance thermoplastic carbon-composite material, which is increasingly being used in the aerospace industry for weight sensitive designs and is also known to offer increased resistance to damage propagation compared to epoxy based materials [10, 11]. Importantly, thermoplastics allow the use of out-of-autoclave processing techniques such as automated tape laying (ATL), a relatively new processing method based on the in-situ consolidation of plies. This is carried out by a computer controlled robot which typically applies pre-preg tape to a heated mould placed on a revolving mandrel, using a heat source such as a laser which is focused on the ply lay-down area. Unlike autoclave processing, consolidation occurs at the point where the robotic head first heats, then melts and finally consolidates and cools the incoming tape, as opposed to

1 processing the entire laminate simultaneously. This facilitates the manufacture of large structures without
2 the investment required for a large autoclave of several metres diameter. Thus the technique is well suited
3 to producing components such as cryo-tanks. The main drawbacks of this technique include the potential
4 for poor ply adhesion due to insufficient melting and adhesion and the presence of significant residual
5 stress gradients due to non-uniform cooling [8, 12, 13]. The tape-laying process itself can also result in
6 gaps due to overlapping plies which can result in high void contents. These issues can often lead to
7 composite laminates of a lower general quality than those produced in an autoclave [9, 14].

14 CF/PEEK, due to its high processing temperature and semi-crystalline nature, exhibits significant
15 property variation with temperature. Residual stress build-up for CF/PEEK laminates begins below the
16 stress free temperature (SFT), which is approximately 315 °C [15]. This is far above the glass transition
17 temperature of 143 °C, which usually marks the point of residual stress formation for amorphous
18 polymeric composites. Thus, using this material for cryogenic applications can involve having to design
19 for thermal residual stresses due to temperature changes in excess of 500 °C. The difficulty in accurately
20 characterising material properties over such a wide temperature range means that little experimental data
21 is available from the literature, particularly for relatively novel materials such as tape-laid CF/PEEK.

22 This work aims to advance the design and analysis of linerless composite cryo-tanks by combining the
23 extensive material characterisation of a tape-laid composite with a novel numerical methodology capable
24 of predicting composite laminate damage and permeability. This approach represents a significant
25 departure from existing analysis methods such as unit cell, first-ply-failure and continuum analyses [6,
26 16-21] by allowing the discrete damage modelling of large structures using detailed material data inputs.
27 An optimised cryo-tank design is also presented, which accounts for the thermo-mechanical stresses
28 resulting from processing, fuelling and internal pressurisation. A sub-model meso-scale damage analysis
29 shows that the optimised tank design is capable of preventing fuel leakage after exposure to cryogenic
30 temperatures and internal pressurisation.

31 **2. Material characterisation**

32 **2.1 Overview of material properties**

33 Measurements of temperature-dependant mechanical, thermal and fracture properties of CF/PEEK
34 materials have been collated from several sources in tables 1 and 2. Using the properties of the tape laid
35 Suprem IM7 [22] at 25 °C from table 1 as a base, temperature-dependant data is generated by

1 interpolation and normalisation using fitting functions across a range of temperatures for available
2 material data. Table 3 presents the resulting interpolated temperature dependant data which is used in
3
4 subsequent modelling work, described in Section 3.
5

6
7 When compared with previously published material data for a similar grade of CF/PEEK processed using
8
9 an autoclave [26], the tape-laid material exhibits lower strength values, particularly in the matrix-
10
11 dominated directions. Transverse tensile strength alone was found to reduce by a third for the tape laid
12
13 material. The increased presence of manufacturing defects resulting from the tape-laying process
14
15 contributes to this property degradation.
16

17 **2.2 Defect characterisation**

18
19 The void and inclusion content for several types of tape-laid CF/PEEK laminates were measured using
20
21 3D X-ray computed tomography (CT). This non-destructive testing technique allows full internal
22
23 characterisation of a specimen based on the varying densities of its constitutive material phases. The
24
25 specimens (see Table 4) were manufactured from a Suprem T/60%/IM7/PEEK/150 material with 0.14
26
27 mm ply thickness and included:
28

- 29 • Two unidirectional coupons, named UD1 and UD2 from a flat plate (16 ply, 34 mm × 27 mm)
- 30
- 31 • Two $[45^{\circ}/-45^{\circ}/90^{\circ}/0^{\circ}/90^{\circ}/0^{\circ}/90^{\circ}/0^{\circ}/90^{\circ}]_s$ coupons QI1 and QI2, from a flat plate (18-ply, 34
- 32
- 33 mm × 27 mm)
- 34
- 35 • One Unidirectional hoop wound section (16-ply, 500 mm diameter)
- 36
- 37
- 38
- 39

40 A KUKA KR 180 R2900 robot with a laser-line diode laser module (LDM) 3000W system operated by
41
42 the Irish Centre for Composites Research (ICOMP) and based at the University of Limerick [14], Ireland,
43
44 was used to manufacture the specimens. The nominal process parameters included a lay-down speed of
45
46 6m/min, a target temperature of 420 °C, a tool temperature of 280 °C, a roller pressure supply of 4.5 bar.
47
48 and a laser power of 500 W.
49

50
51 The CT scans were carried out using a *Phoenix M nano/microtom* at a scan resolution of 33 µm. The X-
52
53 ray gun was rated at 180 kV, with scans being carried out at 160 kV and 28 µA, giving a scan power of
54
55 4.5 W. A total of 1,000 images were generated for each scan over a 360° field of view, for a total scan
56
57 time of 67 minutes. The tomographical reconstruction was carried out using *Davos* software, whilst
58
59
60
61

1 volume rendering was completed using *VGStudio MAX 2.2*. Fig. 1 shows a rendered CT scan of voids in
2 the UD1 and hoop specimens.
3

4 Complete characterisation of individual void morphology and total void volume content within the scan
5 area is possible using this technique. Table 4 provides details of the average x, y and z dimensions of the
6 voids (\bar{x} , \bar{y} , \bar{z}) and their respective standard deviations ($\sigma(x)$, $\sigma(y)$, $\sigma(z)$) for each specimen type as
7 measured using the volume-rendering software. The total void volume as a percentage of the specimen
8 volume is also provided.
9

10 Although all specimens were found to have a void volume content below the 1.5% considered generally
11 acceptable for aerospace components, they compared relatively poorly with similar autoclaved specimens
12 which were found to have an order of magnitude lower void contents [28]. The unidirectional and hoop
13 specimens were found to have lower void contents, likely due to the absence of air gaps, which are
14 discussed in Section 2.3. As expected, the void geometry was found to be related to the laminate lay-up,
15 with the largest dimension of the voids being aligned with the fibre direction (x) and the smallest
16 dimension being in the thickness direction (z). This trend also carried through to the computed standard
17 deviations of the void dimensions. The specimen QI2 was found to have a particularly high void content
18 due to a large number of gaps being present, which in turn skewed the measured void morphology. A
19 more detailed overview of void morphology for the UD1 and QI1 specimens is provided in Fig. 2. Fig. 2
20 (a) and (b), which show the distribution of void volumes within the specimens. The vast majority of voids
21 have a volume of less than 0.05 mm^3 , although a large proportion of the total void volume is contained
22 within a minority of large voids. This is particularly true for the QI1 specimen, where less than 10% of
23 voids account for 64% of the total void volume. Fig. 2 (c) shows the relationship between void sphericity
24 and void radius, where sphericity is defined as the ratio between the surface of a sphere with the same
25 volume as the defect and the surface of the defect. Smaller voids tend to be more spherical while larger
26 voids are more elongated and elliptical. It should be noted that inclusion content for all specimens was
27 found to be negligible.

52 **2.3 Microcracking and gaps**

53 The specimens were also examined for the presence of microcracks and gaps, which can arise due to
54 processing. One side of each of the UD and QI specimens was polished to facilitate optical examination
55 under a microscope. No microcracks or gaps were observed in the UD specimens. Minor damage was
56
57
58
59
60
61

1 detected in the QI1 and QI2 specimens as-processed in the form of 3 surface microcracks across all
2 polished surfaces. Six gaps were detected in the QI1 specimen and seven in the QI2 specimen, with QI2
3 containing several notably wide gaps, as can be seen in Fig. 3. The QI1 and QI2 specimens were also
4 exposed to a single cryogenic cycle via immersion in liquid nitrogen (LN₂) from -196 °C to 40 °C in
5 order to examine the resulting damage formation and its implications for laminate permeability.
6
7

8
9
10 Moderate damage accumulation was observed post-cycling with transverse microcracks forming in the
11 outer and central plies as shown in Fig. 4 (a), although the presence of through-thickness crack networks
12 was not obvious. However, the location of gaps in otherwise un-damaged plies led to a reduction in the
13 number of pristine barrier plies, with the consequence of decreased resistance to leakage if the material
14 was used for a cryo-tank. Average crack opening displacement (COD), shown in Fig. 4 (b), was found to
15 be relatively low when compared to previous work [28]. This is due to the constantly varying ply
16 orientation and lack of ply blocking. Although the likelihood of through-thickness crack networks
17 forming in the laminates is greatly increased by the presence of gaps, which themselves can be over 100
18 times the width of microcracks, their presence can be significantly reduced by appropriate adjustment of
19 the tape placement width.

31 **3. Cryo-tank modelling**

32 **3.1 Tank design**

33
34
35
36 Aside from external launch and structural loads, the primary design considerations for cryo-tanks for
37 space applications are temperature and pressure based. Unlike conventional composite overwrapped
38 pressure vessels (COPVs), which require a liner to prevent fluid leakage [29], linerless composite tanks
39 must remain impermeable without the presence of additional barrier materials. Additionally, due to the
40 large temperature difference between processing temperatures and the cryogenic fuel, thermal loading is
41 the dominant load form. Internal tank pressure is generally far below the levels that typical COPV designs
42 can tolerate. For this reason, mitigation of thermal stress is seen as a key design requirement for linerless
43 cryo-tanks.
44
45
46
47
48
49
50
51

52
53 In this work, a design for a scaled-down version of a cryo-tank for a RLV is presented. The tank has a 500
54 mm diameter and holds approximately 90 litres of cryogen. A symmetric 20-ply lay-up, giving a wall
55 thickness of 2.8 mm, is used. This is in order to ensure structural integrity at a maximum expected
56 operating pressure of 10 bar. Both material processing and tank fuelling are represented by a two-stage
57
58
59
60
61

1 thermal load as shown in Fig. 5. This is due to the residual stress formation which can occur in
2 thermoplastic laminates from the SFT to ambient temperature. Different convection coefficients (h) are
3 used to simulate the rate of cooling for each stage, with significantly more severe thermal gradients
4 associated with the fuelling stage than the processing stage.
5
6

7
8
9 The design of the tank lay-up is key to preventing damage formation and leakage. Assuming a leak-
10 before-burst criterion focused on the cylindrical portion of the tank (Fig. 6), the following steps were
11 adopted in designing the general stacking sequence:
12
13

- 14
15 1. Limiting of thermal stress is prioritised due to the large temperature change. Therefore ply-angle
16 variation is minimised throughout the lay-up. A unidirectional lay-up is most suited for the
17 reduction of laminate level thermal stress, but is not practical for resisting internal pressurisation
18 loads.
19
20
- 21 2. For an internally-pressurised tank with closed ends, the nominal hoop stress is twice the axial
22 stress. Therefore an optimal unidirectional lay-up should have the fibres orientated in the hoop
23 direction.
24
25
- 26 3. The axial stress due to internal pressure then becomes the limiting design failure issue due to the
27 possibility of transverse failure of the hoop-orientated plies.
28
29
- 30 4. This axial stress is reduced by rotating the angles of specific hoop plies towards the axial
31 direction. This must be designed to also balance with increasing thermal stresses due to the
32 increasing ply-angle variation.
33
34
35
36
37
38
39
40

41 The wound composite modeller (WCM) [30], a plugin for Abaqus FEA software, was used to rapidly test
42 prospective lay-ups based on the latter design steps. As is the case with conventional filament winding
43 methods, plies were grouped in opposing pairs according to the following general lay-up: $[90^\circ_2/\pm\theta^\circ/\pm\theta$
44 $^\circ/90^\circ_2/\pm\theta^\circ]_s$. Fig. 7 shows the predicted stress distributions transverse to the fibre direction through the
45 cylindrical portion of the tank wall for several lay-up iterations at maximum expected operating loads.
46
47
48
49

50
51 Ensuring that the transverse tensile strength of the composite is not exceeded is an important factor in
52 limiting matrix microcracking and hence leakage. Fig. 7 shows a clear trend in the relationship between
53 decreasing ply angle variation and decreasing peak transverse stress. Conventional COPV lay-ups using a
54 mixture of hoop and low-angle helical plies (plies between 5° and 30°) are shown to be unsuitable for the
55 unique demands of cryogenic fuel storage, where the minimisation of thermal stress is critical. As the
56
57
58
59
60
61

[90°₂/±75°/±75°/90°₂/±60°₂]_S lay-up was the only stacking sequence in which the transverse strength of the composite was not exceeded in every ply, it was selected for more in-depth analysis via the damage sub-model outlined below in Section 3.2. It should be noted that for certain conventional filament winding methods, such a high-angle helical lay-up would not enable full coverage of the polar boss regions around the ends of the tank. Additional reinforcement in the form of pre-fabricated doilies [1, 31] would be required at the polar bosses in order to ensure continuation of the desired lay-up from the cylindrical section to the dome section of the tank.

3.2 Combined XFEM-SCZM damage method

A combined XFEM (extended finite element method) and SCZM (surface cohesive zone model) approach to damage modelling in composite laminates is developed here. Modelling is focused on the meso-scale, with XFEM being used for microcrack initiation and propagation (intra-laminar failure) and SCZM for mixed-mode delamination growth between plies (inter-laminar failure). This methodology allows the discrete modelling of microcracks and hence prediction of laminate permeability. It is also applicable to relatively large-scale structures such as cryo-tanks (Fig. 8). The general XFEM-SCZM approach is implemented within an adapted form of the general purpose, non-linear finite element code, *Abaqus v6.14*, as is described in detail in previous work [32, 33].

However, due to the complex thermo-mechanical load state present in the cryo-tank, the original method [33] has been improved here to incorporate a more sophisticated mixed-mode compression-shear matrix failure criterion. Oblique fracture planes aligned with the fibre angle are now permitted, along with the usual transverse microcracking perpendicular to the ply interface. Fig. 9 illustrates the main matrix failure modes modelled using XFEM for an assumed two-element model.

This enhancement is implemented through a user defined damage initiation sub-routine (UDMGINI) [34] within the general XFEM framework. A crack is assumed to initiate when the relevant fracture criterion, f , is exceeded, where f_t is the tensile failure criterion and f_c is the compressive failure criterion. This criterion is based on the Hashin failure criteria [35] for matrix failure:

- For tensile matrix failure ($\sigma_{22} + \sigma_{33} > 0$), $f_t \geq 1 = \text{failure}$

$$f_t = \frac{(\sigma_{22} + \sigma_{33})^2}{Y_f^2} + \frac{\sigma_{23}^2 - \sigma_{22}\sigma_{33}}{S_{23}^2} + \frac{\sigma_{12}^2 + \sigma_{13}^2}{S_{12}^2} \quad (1)$$

- For compressive matrix failure ($\sigma_{22} + \sigma_{33} < 0$), $f_c \geq 1 = \text{failure}$

$$f_c = \left[\left(\frac{Y_c}{2S_{23}} \right)^2 - 1 \right] \left(\frac{\sigma_{22} + \sigma_{33}}{Y_c} \right) + \frac{(\sigma_{22} + \sigma_{33})^2}{4S_{23}^2} + \frac{\sigma_{23}^2 - \sigma_{22}\sigma_{33}}{S_{23}^2} + \frac{\sigma_{12}^2 + \sigma_{13}^2}{S_{12}^2} \quad (2)$$

where σ and associated subscripts refer to conventional transverse tensile, compressive or shear stress in the local coordinate system. Y_T and Y_c are the tensile and compressive strengths of the matrix and S and associated subscripts are the shear strengths of the matrix. Depending on the failure mode, the angle of the fracture plane, denoted as α in Fig. 6.9, can also be pre-defined and will align parallel to the local '1' or fibre direction, which is at an angle β to the global 'x' direction.

3.3 Microcrack initiation

Two distinct methods of simulating random microcrack initiation within the cryo-tank, based on methods outlined in [33], are used. These methods have been adapted for use with the tape-laid CF/PEEK material described in Section 2. The first approach is based on the inherent random distribution of the material fracture strength in the form of a continuous probability Weibull distribution, which is volume-adjusted to account for the size effects associated with mesh density of the FE damage models. The two properties required to generate a fracture strength distribution for a given material using this method are the mean fracture strength of the material, $\bar{\sigma}_0$, and a Weibull modulus, m . The transverse tensile strength of the tape-laid CF/PEEK was taken here as the mean fracture strength, which is identified as 41 MPa at ambient temperature. Due to the lack of experimental data in the literature on the material, an inverse identification procedure was adopted to estimate the Weibull modulus of the material. Based on the tensile test geometry described in [33], successive tensile test simulations were performed, iteratively adjusting the Weibull modulus for a prescribed strength distribution until the predicted average bulk transverse stress at failure matched the measured value of 41 MPa. Fig. 10 (a) shows the resulting Weibull fracture strength distribution based on the identified m value of 3.5 for 5,000 elements in an FE mesh. Note that a limited distribution is used in simulations in order to prevent the material from having a transverse strength above 100 MPa, taken as the upper limit of physically realistic values.

The second approach is based on an elemental representation of defects whereby voids are represented via reduced element stiffness, leading to stress concentrations. Voids can be represented by ellipsoids within an element volume (Fig. 10 (b)), whose x, y and z dimensions are based on the values of Table 4. The

voids are randomly distributed throughout the material in the finite element model and act to reduce element stiffness in accordance with the following:

$$E_1^* = \left(1 - \frac{\pi yz}{4}\right) E_1 \quad (3)$$

$$E_2^* = \left(1 - \frac{\pi xz}{4}\right) E_2 \quad (4)$$

$$E_3^* = \left(1 - \frac{\pi xy}{4}\right) E_3 \quad (5)$$

where E_i^* is the reduced element stiffness, E_1 is the fibre direction modulus and E_2, E_3 are the transverse moduli.

3.4 Tank damage and permeability

The damage sub-model consists of $1/8$ th of the cylindrical portion of the cryo-tank, which corresponds to a section 100 mm wide as shown in Fig. 6. Symmetry boundary conditions are used to constrain the sub-model and to ensure accurate response in relation to the full cryo-tank. Although the lay-up consists of 20 plies, only 15 distinct plies are required due to ply pairing e.g. combining two adjacent 90° plies to form one thicker ply. A SCZM is defined between each ply. The mesh density for each ply was chosen to allow at least 5 microcracks per cm of cylinder width or circumference. This crack density corresponds to the maximum crack density observed in heavily damaged cryogenically cycled CF/PEEK laminates in [28]. Each model comprises 150,000 3D solid elements, with simulations being performed on twenty-four 2.4GHz cores on a cluster based at the Irish Centre for High Performance Computing (ICHEC). Model run-times varied between 36 and 72 hours depending on the level of damage formation. Sequential thermo-mechanical analyses were required in order to model the transient thermal behaviour shown in Fig. 5.

Simulations were performed using the two different microcrack initiation methods described in Section 3.3. Volume-adjusted Weibull fracture strengths, generated using the Weibull modulus of 3.5, were randomly assigned to each element in the FE mesh. A number of the lay-ups of Fig. 7 were modelled using this method, as shown in Fig. 11.

In accordance with the transverse stress profiles in Fig. 7, significant microcracking was observed in the $[90^\circ_2/\pm 30^\circ/\pm 22^\circ/90^\circ_2/\pm 15^\circ_2]_S$ lay-up, with damage accumulation reaching such a level that the simulation

1 was halted due to the estimated convergence time. The $[90^{\circ}_2/\pm 75^{\circ}/\pm 60^{\circ}/90^{\circ}_2/\pm 45^{\circ}_2]_S$ and
2 $[90^{\circ}_2/\pm 70^{\circ}/\pm 50^{\circ}/90^{\circ}_2/\pm 30^{\circ}_2]_S$ lay-ups performed better, with less microcracking at equivalent loading.
3
4 However damage reached an unacceptable level before the load step was complete. Delamination
5
6 initiation areas can be seen in Fig. 11 for these simulations. The $[90^{\circ}_2/\pm 75^{\circ}_2/90^{\circ}_2/\pm 60^{\circ}_2]_S$ lay-up achieved
7
8 convergence promptly, with moderate levels of microcracking visible through the tank wall. In order to
9
10 investigate damage formation in this lay-up, an additional four simulations were undertaken using the
11
12 Weibull method (Fig. 12) and three using the direct defect method (i.e. for more random distributions of
13
14 fracture strengths) (Fig. 13). The void dimensions from Table 4 for the QI2 specimen were used for the
15
16 direct defect simulation, giving an average void content of between 1.45%, the highest measured by the
17
18 3D X-ray CT analysis.
19
20

21 A qualitative analysis of the damage formation shown in Figs. 12 and 13 indicates consistent
22
23 microcracking for each method within their respective sample set, with low-to-moderate damage levels
24
25 visible in most plies. A quantitative analysis of the average ply-by-ply crack density for each method is
26
27 given in Fig. 14. The variation in crack density for the Weibull method mirrors the transverse stress
28
29 distribution for the lay-up shown in Fig. 7, with the centre $\pm 60^{\circ}$ plies exhibiting the highest number of
30
31 microcracks. It is also worth noting that the average crack densities of the plies on the inner surface of the
32
33 tank were higher than their corresponding plies on the outer surface. Although microcracks initiated in
34
35 every ply throughout the tank wall, the low crack density of the outer plies meant that no through-
36
37 thickness crack networks were detected for any of the five Weibull simulations, implying negligible
38
39 permeability for the design. Crack density values taken from the direct defect simulations show the same
40
41 microcracking trend for the centre plies. However no microcracks were observed in the hoop or $\pm 75^{\circ}$
42
43 plies. This was due to the void induced stress concentrations being of insufficient magnitude to initiate
44
45 cracking in these plies, despite the maximum measured void content being used in the simulations. In this
46
47 case, the Weibull method can be considered a more thorough approach to damage and permeability
48
49 prediction.
50
51

52 **4. Conclusions**

53
54 A combined experimental and numerical method for the prediction of damage and permeability in
55
56 internally pressurised linerless cryogenic tape-laid tanks is presented. A detailed characterisation of a tape
57
58 –laid CF/PEEK material is presented, with temperature-dependant material properties covering the range
59
60
61
62
63
64
65

1 from processing to cryogenic temperatures. Optical micrography and 3D X-ray CT were used to
2 investigate the defect content of the material as well as damage due to cryogenic cycling. Void content of
3 the tape-laid material was found to be an order of magnitude higher than for comparable autoclave
4 processed material, although similar trends in void morphology were observed. Transverse microcracks
5 were also present throughout the test specimens post-cycling.
6
7
8
9

10 A detailed tank design, based on reducing the transverse stress throughout the tank wall, was developed.
11 Unlike lay-ups typically used for COPVs, a combination of hoop and high-angle helical plies were found
12 to be most efficient at reducing transverse stress levels due to combined thermo-mechanical loading. A
13 sub-model of the cryo-tank was developed to predict intra- and inter-ply damage formation based on a
14 novel XFEM-SCZM methodology. The material properties and defect distributions of the tape-laid
15 material were used as inputs for the model. Two methods of modelling microcrack initiation were
16 employed: a Weibull distribution of fracture strengths method and a void-based stiffness reduction
17 method. Several lay-up variations were tested using the modelling technique. The optimised high-angle
18 helical tank was shown to be least susceptible to through-thickness microcrack formation and hence
19 cryogen leakage.

Figure captions

Figure 1 3D X-ray-CT scan of voids present in tape-laid UD1 (top) and hoop CF/PEEK specimens (bottom). (Where the x direction is the fibre direction, y is transverse to the fibre direction and z is the thickness direction).

Figure 2 (a) Distribution of void volumes below 0.1 mm^3 arranged from highest to lowest measured using 3D X-ray CT for tape-laid unidirectional (UD1) and quasi-isotropic CF/PEEK specimens (QI1). (b) Bar chart showing the frequency of voids within a given volume range. (c) Relationship between the sphericity and the equivalent radius of voids from specimens UD1 and QI1.

Figure 3 An optical micrograph of gaps, a surface microcrack and voids in the tape-laid CF/PEEK specimen QI2, as processed (top), a micrograph of a gap and two transverse microcracks present in specimen QI2 after exposure to a single cryogenic cycle (left) and rendered 3D X-ray CT scan of microcracking and gaps in the same specimen (right).

Figure 4 (a) Ply level microcracking detected using micrographs of QI1 and QI2 after cryogenic cycling. Gaps are also included. (b) Crack opening displacement and gap width measurement from cycled specimens. Ply groups 1 - 9 refer to symmetric ply pairs i.e. ply group 1 comprises the outer 45° plies.

Figure 5 Plot of temperature on the inner and outer surfaces of the tank wall due to the two-stage cooling related to the processing and fuelling windows. The increase in internal tank pressure is also shown.

Figure 6 Schematic showing the location of the cylindrical sub-model in relation to the full cryo-tank. Tank design is focused on this sub-region.

Figure 7 Transverse stress distributions through the cylindrical portion of the tank wall for several lay-up variations under the loading described in Fig. 5. The numbers in the legend refer to the angles $\pm \theta^\circ$ in the general 20-ply lay-up $[90^\circ_2/\pm \theta^\circ/\pm \theta^\circ/90^\circ_2/\pm \theta^\circ_2]_s$. QI refers to the test specimen lay-up $[45^\circ/-45^\circ/90^\circ/0^\circ/90^\circ/0^\circ/90^\circ/0^\circ/90^\circ]_s$.

Figure 8 The combined XFEM-SCZM method facilitates prediction of microcracking and delamination in large scale structures such as the cylindrical sub-model of the cryo-tank shown above.

Figure 9 Schematic showing the microcrack morphology related to tensile, compressive and shear loading in a two-element model. Oblique fracture planes are orientated at a prescribed angle α (i.e. 45° for transverse compression) and are parallel to the ply fibre angle β .

Figure 10 (a) De-limited and limited Weibull distributions used in modelling. The element fracture strengths are ordered smallest to largest. (b) Schematic of an air void within an element. The reduction in

element stiffness is based on the dimensions of the void as measured using 3D X-ray CT and forms the basis of the direct defect method.

Figure 11 Comparison of through-thickness damage formation from the outer to the inner surface of the tank for several lay-ups showing XFEM microcracking and intensity of inter-laminar forces (SCZM) (red – high; blue – low).

Figure 12 Damage formation in the remaining four Weibull damage models for the $[90^{\circ}_2/\pm 75^{\circ}_2/90^{\circ}_2/\pm 60^{\circ}_2]_S$ lay-up.

Figure 13 Damage profiles for three realisations of the $[90^{\circ}_2/\pm 75^{\circ}_2/90^{\circ}_2/\pm 60^{\circ}_2]_S$ lay-up obtained using the direct defect method, each with an average void content of approximately 1.45%.

Figure 14 Comparison of average crack densities for each ply of the $[90^{\circ}_2/\pm 75^{\circ}_2/90^{\circ}_2/\pm 60^{\circ}_2]_S$ cryo-tank predicted by the Weibull and direct defects modelling methods. Ply 1 is on the inner surface of the tank.

Table captions

Table 1 Measured temperature-dependant mechanical and fracture properties of CF/PEEK materials. E and G are the elastic and shear moduli, TTS and TCS are the transverse tensile and compressive strengths, $IPSS$ and $ILSS$ are the in-plane and inter-laminar shear strengths, G_{IC} and G_{IIC} are Mode I and Mode II fracture toughness. The subscripts 1 and 2 refer to the longitudinal and transverse directions. ¹Suprem Victrex AS4 [23], ²Cytec APC-2/IM7 [24], ³Suprem Victrex IM7 [22], ⁴Suprem Victrex IM7 [23].

Table 2 Measured temperature-dependant mechanical and thermal properties of CF/PEEK materials. E and G are the elastic and shear moduli, ν is Poisson's ratio, ρ is density, SHC is the specific heat capacity, α and k are the thermal expansion coefficients and conductivities. The subscripts 1 and 2 refer to the longitudinal and transverse directions. ¹APC-2/AS4 adapted from [25], ²PEEK/IM7 adapted from [26], ³APC-2/AS4 adapted from [27].

Table 3 Interpolated temperature-dependant material properties for tape-laid Suprem IM7 based on the measured properties in Tables 1 and 2.

Table 4 Mean and standard deviation of the x , y and z dimensions of voids in unidirectional ($UD1$, $UD2$), hoop and quasi-isotropic ($QI1$, $QI2$) tape-laid CF/PEEK specimens measured using 3D X-ray CT. Void volume content is also provided, where possible. *Indicates gaps included in void content.
